University of Pittsburgh

Abstract

*With growing disk and storage capacities, the amount of required metadata for tracking all blocks in a system becomes a daunting task by itself. In previous work, we have demonstrated a system software effort in the area of predictive data grouping for reducing power and latency on hard disks. The structures used, very similar to prior efforts in prefetching and prefetch caching, track access successor information at the block level, keeping a fixed number of immediate successors per block. While providing powerful predictive expansion capabilities and being more space efficient in the amount of required metadata than many previous strategies, there remains a growing concern of how much data is actually required. In this paper, we present a novel method of storing equivalent information, *SESH*, a *Space Efficient Storage of Heredity*. This method utilizes the high amount of block-level predictability observed in a number of workload trace sets to reduce the overall metadata storage by up to 99% without any loss of information. As a result, we are able to provide a predictive tool that is adaptive, accurate, and robust in the face of workload noise, for a tiny fraction of the metadata cost previously anticipated; in some cases, reducing the required size from 12 gigabytes to less than 150 megabytes.*

I. Introduction

Hard disk and storage system performance concerns, both in terms of latency access and power consumption, continue to gain importance for modern computer systems. Both hardware and software efforts continue to try to reduce latencies and response times while demanding greener, more efficient use of resources. Many system software projects involve tracking and

profiling workloads in order to predict and identify access patterns, both at the file and at the block level. Such techniques include data placement, both static as well as dynamic, caching and prefetching, as well as data replication and shuffling. But with growing disk and storage capacities, the volume required by metadata for tracking all blocks in a system becomes a daunting task in its own right. Further, while hardware advancements provide significantly larger storage systems, the ratio of used storage has been shown to remain stable, even with these larger disks [1].

In previous work, we have demonstrated a system software effort in the area of predictive data grouping for reducing power and latency on hard disks [2]. The structures used, very similar to prior efforts in prefetching and prefetch caching, track access successor information at the block level, keeping a fixed number of immediate successors per block. While providing powerful predictive expansion capabilities and being more space efficient in the amount of required metadata than many previous strategies, there remains a growing concern of how much data is actually required. In this paper, we present a novel method of storing equivalent information, *SESH*, a *Space Efficient Storage of Heredity*. This method utilizes the high amount of block-level predictability observed in a number of workload trace sets to reduce the overall metadata storage by up to 99% without any loss of information. As a result, we are able to provide a predictive tool that is adaptive, accurate, and robust in the face of workload noise, for a tiny fraction of the metadata cost previously anticipated; in some cases, reducing the required size from 12 gigabytes to less than 150 megabytes.

II. Motivation

Optimizing storage system performance in the face of varying workloads requires the accurate tracking and

exploitation of patterns in data access behavior. Such information is useful for a broad range of applications, including caching, placement, workload shaping, data collocation and migration. Unfortunately, tracking access behavior and predicting future access behavior can result in large metadata demands. This is true when dealing with data at the granularity of files and objects, but quickly becomes unmanageable when attempting to monitor block-level access behavior in large storage systems. An explosion in metadata volume is doubly problematic when we consider that retrieving and updating such metadata can suddenly become an additional burden upon the storage subsystem. On the other hand, arbitrarily limiting the volume of metadata being maintained will only allow for optimizations to data within a current hotspot, the currently active working set, which is arguably less in need of pattern discovery and placement optimization (due to the effectiveness of even basic caching schemes on such subsets). This inevitably precludes the opportunity to discover longer-term patterns across less intensely active regions.

To improve the accuracy of placement and collocation decisions, and improve the overall performance of predictive analysis of data access patterns, we wish to maintain as much metadata as possible, but only if it is useful. Our previous work on predictive data grouping [2] demonstrates one such strategy that stores a number of direct block successors for each data access. Our strategy shows promise in the area of data grouping, and is similar to previously explored strategies in prefetching and prefetch-caching strategies adopted by Kroeger *et al* at the file level [3], [4]. We present a study of how it is feasible to reduce the metadata requirements of our strategy in the face of block-level I/O workloads. The structures used in our work are reminiscent of the limited-length queue of access successors in the *Recent Popularity* strategy adopted in [5]. Such single-successor strategies are often chosen for their efficiency benefits over multicontext modeling, yet still require huge amounts of storage. Minimally, we would need to track the root block's id, which could simply be a translated location within an array, and the queue of accesses, each of which is a block id. Thus, the total storage space would be the number of successors stored, s , times the total number of blocks, t . For modern systems, this metadata volume is too large. For a 4 TB disk array, assuming a block size of 4 KB, this would mean storing information for 1 billion blocks. Assuming a 64-bit address, this system would require 8 GB of space *just for storing a single successor*. We address the issue of metadata volume

requirements in *SESH* by observing that most blocks share two properties...

- 1) They only have a single successor.
- 2) The only successor they have is the next sequential block.

Using this information, we are able to drastically reduce the total size needed for our predictive information while incurring little overhead. Further, our strategy scales better in the number of successors tracked.

The remainder of this paper is organized as follows. Section III discusses prior art related to *SESH*. Section IV briefly describes the structures used and details our experiments. Results are presented in Section V and we conclude with Section VI.

III. Background and Related Work

A study on graph-based access predictors was first presented by Griffioen and Appleton [6]. These predictors were used to provide sufficient lead-time to render the prediction useful for prefetching as well as managing access patterns spanning multiple applications. The use of the last successor model for file prediction, and more elaborate techniques based on pattern matching, were first presented by Lei and Duchamp [7]. Similar work has been done researching a last successor predictor, finite multi-order context modeling (FMOC) models from branch prediction methods, and a partitioned context model (PCM) [3]. While a "last successor" strategy predicted with surprising accuracy, there tends to be enough noise in an access stream to confuse it [8]. A more stable predictor, Noah, is presented that removes this noise by predicting only if a stability condition is satisfied.

Previous work has also shown that comparing two different predictors is non-trivial. To aid in this dilemma, three measures of prediction accuracy were developed; general accuracy and specific accuracy [5] and effective-miss-ratio [9]. General and specific accuracy were used to compare Noah with last successor and first successor [5]. It is noted that Noah suffers from non-decreasing general accuracy for high stability parameters. A new predictor, *Recent Popularity*, is shown to solve this problem. It is also noted that *Recent Popularity* adapts quicker with changing workloads than Noah. To benefit from this robustness and adaptability, our techniques use variants on *Recent Popularity* for gathering data for prediction.

Similar work on the aggregating cache differs from related work on predictive prefetching systems, but uses analogous structures to Griffioen and Appleton's

graph-based scheme [6]. Kroeger and Long [3] compared the predictive performance of the last successor model, Griffioen and Appleton’s graph-based strategy, and new techniques based on context modeling and data compression [10]. The earliest proposed use of data compression strategies to predict disk accesses was presented by Vitter and Krishnan [11], [4]. Shriver *et al.* [12] has provided analytical reasoning for the benefits of read-ahead buffering and prefetching. Other recent work on ASP [13] presents a study of a strip prefetching scheme for striped disk arrays. The authors show that combining separate management of prefetched and regular cache lines with a culling scheme using differential feedback similar to the adaptive marginal utility used in SARC [14]. Such prefetching of data is not without costs, many of which are addressed in ASP. Any prefetching strategy must have a reasonable lead time in order to retrieve data before it is actually requested. Additionally, any benefit from this prefetching, like spin-down techniques, lie directly on the data path. Our strategy enables the decoupling of the strategy from the data path, allowing us to shut down any regrouping while still benefitting from previous efforts to properly cluster data.

Recent work has shown advances toward utilizing device-level knowledge of physical data layout. Prediction for both caching purposes and prefetching purposes have begun emphasizing spatial locality as having a higher utility than a random access; that is, a block likely to be accessed next that happens to be close to the current location of the disk head has much higher usefulness than a similarly likely block that exists far away. DULO [15] presents a buffer cache management scheme that exploits both temporal and spatial locality, while DiskSeen [16] presents work utilizing similar table structures for use of predictive prefetching. DiskSeen fetches at the device level, and is designed to be synergistic with file-level prefetching strategies. More recent work on TaP [17] describes using a separate data structure to store previous addresses in order to identify sequential data streams without having to use precious cache space to do so. Our work seeks to increase the likelihood of spatially close blocks, and would be highly beneficial to such location- and stream-aware strategies.

Traditional research to improve performance of hard disks by modifying I/O workloads include scheduling strategies such as SSTF, SCAN [18], C-SCAN [19], and LOOK [20]. More recently, approaches for decreasing the growing impact of rotational delay have been presented [21], [22], [23], [24], [25]. These efforts are

considered orthogonal to our current and previous work on prediction and data regrouping.

The use of prediction as a means of workload shaping to reduce power consumption has been proposed by Flinn and Satyanaryanan [26] and also Lorch and Smith [27]. These suggestions focused on the ability of prefetching data to allow for increased idle-time periods, which in turn would hopefully allow greater opportunities for disk spin-downs. Similarly, recent work by Weissel *et al.* [28], and Papathanasiou and Scott [29], attempts to actively modify the workload and increase workload burstiness to increase opportunities for disk spin-down. Predictive methods such as these are expected to benefit from metadata such as that used by this project.

The desire to place related data together on disk is traditionally accepted as a wise storage-system goal, and recent work indicates that its uses continue to present themselves [30], [16], [15]. For example, work by Kandemir *et al.* [30] focuses on utilizing disk layout knowledge at compiler time for data intensive applications, notably scientific applications.

Access patterns can be used to rearrange tracks on the disk [31], a problem known to be NP-Hard [32], to improve on the organ-piping method [33], detailed and discussed in depth by Wong [34]. Such patterns can also be used to identify which files to move to tertiary storage [35]. Other forms of disk management include storing data that does not cross track boundaries [36] as well as how to extract that information and use it as stripe unit boundaries [37], storing inodes by embedding them in their directory, and grouping together small files on disk to be read as one [38]. It has been demonstrated that it is possible to separate inodes from data over a distributed system [39].

Early data placement and predictive grouping studies attempted to use frequency of access as an estimated likelihood in order to optimally place high-demand data. The optimum arrangement of files on disk was originally a manual task, placing popular files near the center of the disk cylinder. The necessary automation of this process has been addressed by Staelin and Garcia-Molina [40], [41], [42], whose work dealt with models that provided optimal placement of files where accesses were independent. However, data accesses often involve dynamic relationships, where access dependencies change over time. Berkeley’s FFS [43], [44] includes attempts to cluster related data and metadata into cylinder tracks on a disk. However, these approaches typically require disjoint sets as groups. Our approach makes no such constraints, allowing

replication between groups formed, although not within them. Similar replication was performed by Akyürek and Salem in 1995, where popular “hot” blocks were copied to a common disk area to improve disk performance [45]. However, this study was based only on the global popularity, or percentage of access, rather than inter-file relationships. Dynamic groups [46] attempt to exploit inter-file relationships, but required explicit application hints to determine group membership. Examples of efforts in automated grouping include C-FFS [38] (collocating FFS), which bases grouping on a directory-membership heuristic, and Hummingbird [47] which utilizes the underlying structure of web files. In contrast, our model does not require any knowledge of underlying data structure, as our grouping mechanism can establish relationships based on observed access behavior, as opposed to inference from file location or content.

IV. Experimental Setup

Our goal is to develop space-efficient structures for tracking metadata, specifically for predictive information. Ideally, these structures would incur little to no overhead while maintaining undiminished usefulness. Further, we seek to define, in a general case, what the expected benefits of these structures would be. Finally, we endeavor to verify our expectations by testing working implementations against realistic workloads in order to determine how effective our data pattern exploitation techniques would be at reducing metadata volumes in real systems. This final goal can be met by testing our strategies on workload trace sets gathered from real systems, rather than drawing from a distribution or synthetic function.

This section describes our strategy by discussing the structures we have developed as well as an estimated reduction formula. We then detail the different trace sets used to evaluate our current implementations. Finally, we explain our metadata volume calculations.

A. Data Structures

Several new data structures were designed for this project. The *Optimal Expansion Tree*, or *OpExTree*, is the base structure used in our previous efforts for tracking metadata for predictive data grouping. The *Dynamic Bitmap* is a functional equivalent to a normal bitmap, but with the advantage of being dynamically allocated and able to spontaneously grow or shrink. The *Dynamic Region* is used to map a fixed number

of bits to some id. Finally, the *SESH* structure is the combination of the above structures used to decrease the size of the necessary metadata required. Following is a brief discussion of each structure.

1) *Optimal Expansion Tree*: Our standard metadata storage structure consists of a root id, or the element’s block number, and an array of immediate successors, or children. The structure is based on the *Recent Popularity* strategy from earlier work on predictive caching and prefetching [5], and was chosen for its robustness to signal noise and speed of adaptation to changing workloads.

Children are in the form of block numbers that occurred directly after the root id. While our structure allows this array to be unbounded, we limit the number of children for this project. Additionally, we track how often each child occurred.

Upon seeing a new event’s successor, we add it to the tree by

- 1) Updating the appropriate count, or
- 2) Adding a new child to the successor array and setting the appropriate count to 1.

In the case of a bounded structure, once we reach the maximum number of children to track, we update the structure by choosing the lowest occurring successor and removing it from the structure. The new successor is then placed into the array and its count is set to 1.

An alternate structure design replaces the successor array with a queue of children, in order of occurrence. Upon reaching the maximum capacity, a dequeue is performed before adding the new event. In this case, the counts are calculated by iterating through the queue on-the-fly. While this method will typically adjust to workload shifts easier, in practice we find the event counting to be a severe bottleneck.

A third alternate structure contains both a queue as well as an array and counts. The queue is used in the same way as above, but dequeued items have their counts deducted, and are removed once their count reaches zero. In practice, we have found that our standard use of only an array very closely approximates this method, and the queue was removed from the standard version.

2) *Dynamic Bitmap*: The *Dynamic Bitmap* structure consists of a count of total number of entries and a hash table of nodes. Each node consists of a simple integer array that represents a region of the functional bitmap. Each set, unset, or check of any particular location is hashed and the appropriate node, if existent, is fetched. On a set, the appropriate integer within the node’s array is adjusted to update the map. If the node does not exist,

Estimated SESH Savings (256GB, 512 Block)

Fig. 1. Estimated calculation of metadata storage space savings on a 256 GB hard drive with a block size of 512 bytes.

it is created. Similarly, on an unset, the appropriate integer is adjusted. If the unset results in an empty node, equivalent to an array of all zeroes, the node is destroyed. On a check, if the node does not exist, zero is returned. Otherwise, the appropriate bit within the existent array is returned.

3) *Dynamic Region*: The *Dynamic Region* structure is very similar to a bitmap. Instead of each bit being used to represent some property of some event, a number of bits are used. This is achieved by utilizing a *Dynamic Bitmap*, and for each event id, we increment some region on the map. For our purposes, we required only that each region denote a count, or integer. Therefore, the only functions we needed were increment, decrement, remove, and check.

4) *SESH, or Space-Efficient Storage of Heredity*: During our work on prediction and data regrouping, we noted that many blocks have only a single successor. Most commonly, this successor happens to be the next block. The *SESH* data structure utilizes this observation by removing such *OpExTrees* from some successor table, typically a hash table, and utilizing a *Dynamic Region* to represent the tree. Some region being non-zero within the *Dynamic Region* structure represents a tree having only a single successor, which happens to be the block directly after the root block in question.

We call the successors stored within the region *heir apperents*. These heir apperents occur the vast majority of the time, and each reduces the amount of metadata required from (minimally) several bytes to only a few bits (on average). As a realistic example, tracking eight successors (64-bit addresses, or 8 bytes) on a 256 GB hard drive with a block size of 512 bytes would require 32 GB of metadata.

$$8 * 8 * (256GB / 512) = 32GB$$

However, each heir apparent would only require, on average, 3 bits. Given below is a estimated calculation for the reduced size, in bits, r , based on the number of blocks, b , the percentage of blocks that only contain heir apperents, p , and the number of successors tracked for each block, n .

$$r = b * (\log(n) * p + (1 - p) * (64 + (64 * n)));$$

Note that this assumes 64-bit block numbers and ignores internal fragmentation within our *Dynamic Bitmap* structure. One note of interest presented by this formula is that when p is very high, the resulting size r becomes very scalable with respect to the number of successors, n . Since most blocks fit into the *Dynamic Region*, increasing n results in a $\log(n)$ increase in the space necessary to store it. The larger structures increase linear to n . Even though these structures are

expected to represent only a small percentage of all items tracked, they *are* expected to dominate the space used fairly quickly. Figure 1 show a 3d plot of a 256 GB hard drive and the metadata required for storing information for all blocks, both before and after reduction, against the number of children tracked and the percentage of blocks that contain heir apparents.

B. Traces

For this project, we used four different workload sets. The *mozart* set consists of a workstation trace gathered using the DFSTrace system [48]. These traces were converted into equivalent block-level traces with block sizes of 512, 4096 (4K), and 8192 (8K) bytes. There were four different original trace sizes; day length, week length, month length, and year length. This set has the appeal of allowing the analysis of our strategies over different definitive time periods as well as allowing us to convert easily to different block sizes.

The second set, *hplajw*, is a block-level workstation trace [49]. This set has the advantage of natively begin a block-level trace, and therefore does not require conversion. However, there is only a single trace length, and lacks any information of original file-system level access information, and therefore cannot be converted to traces of differing block sizes.

The third set, *ranin*, is a trace set we gathered using the standard `fs_usage` command found on Mac OS X. The traces were gathered from November to December, 2007 on a Mac PowerBook G4 running Mac OS X 10.4. The workload represents a typical graduate student workstation, and was used for internet browsing, file editing, code compiling, and running and testing experiments (predominantly C++ programs). While there were a few trace interruptions due to rebooting, including one major software update, the inaccuracies introduced would be negligible. Additionally, the software update had no impact on the `fs_usage` command itself, and any system-level workload shifts due to this update would represent realistic workload shifts experienced by users updating their operating system. Cache activity was gathered, but for these traces they were ignored; only device-level requests were used. These requests were in the form of read and write data and metadata as well as page ins and outs.

The final set, *iTunes*, is a trace set gathered using the same `fs_usage` command. This set was gathered on two different Mac mini G4 workstations, each with 512 MB of memory and running Mac OS X 10.3.9. An iTunes playlist of 148 songs, with a runtime of approximately

14.8 hours, was run on each machine. Traces were gathered from August 31, 2008 to March 23, 2009, resulting in play counts over 300. All disk activity due to iTunes was isolated and recorded. One trace gathered information on a sequential playlist, while the other playlist was shuffled. These traces represent one extreme of predictability, an estimated upper bound on how predictable a realistic workload can be.

Similar to the *mozart* traces, our *ranin* and *iTunes* workloads include information about how large an access was requested, and therefore could easily be converted to equivalent block-level workloads. Perhaps the most interesting block size is 512, which is the natively preferred block size of the hard drives, both for the PowerBook and the Mac minis. However, we included runs on 4K and 8K block sizes for consistency.

Since the `fs_usage` command collects information on *all* devices, these traces do require a bit of attention to what raw device is being accessed. Some devices, such as `/dev/NOTFOUND`, were pruned. All devices that seem viable were included in the test run and mapped to a single device. This mapping was done by giving a 200 GB range to each device. Table I summarizes the devices found in the *ranin* traces and how often each occurred, as well as noting which of these were ignored.

TABLE I. List of all devices found in the *ranin* trace set.

Device	Occurrence Count	Included?
<code>/dev/disk0s3</code>	3746392	Yes
<code>/dev/NOTFOUND</code>	571206	No
<code>/dev/disk2s1</code>	185933	Yes
<code>/dev/disk2</code>	73166	Yes
<code>/dev/disk2s0</code>	10621	Yes
<code>/dev/disk1s1</code>	954	Yes

All of these traces consist of data gathered from actual systems, and as such contain real-world predictability due to user, program, and system behavior, rather than being drawn from a distribution or synthetic function.

C. Calculating Metadata Requirements

Each workload was split into ten sequential segments of approximately equal access counts. The trace was then run through our simulator. Each run consisted of the first segment, followed by running the first and second segments together, and so on until the entire trace was run. At the end of each segment run, the total metadata space used was recorded. Verification results

on each individual segment were also run, but for sake of brevity are not reported.

Each recorded metadata requirement consisted of the calculation of total space used by our *SESH* structure. This includes any and all extra metadata we used for sake of statistics gathering, though these extra object fields are negligible. In calculating these metadata requirements, we count all nodes of all *Dynamic Bitmaps* used in our *Dynamic Regions*, rather than estimating a number of bits per heir apparent as in Figure 1. In order to calculate the projected size of metadata using a hash table of *OpExTrees*, we multiply the number of heir apparents by the total size of the same number of single-child *OpExTrees* and add the appropriate hash table metadata needed to track the extra trees.

V. Results

Our results show that almost all traces of non-trivial size show a drastic decrease in necessary metadata. For most workloads, we can reduce this storage space to only a small percentage of the original space, typically between 1 and 3 percent for smaller block sizes. Table II summarizes the sizes recorded at the very end of the *ranin* workloads, while Table III summarizes the reductions and savings. Figure 2(a) illustrates the difference between the projected metadata requirements and the reduced space on the *ranin* traces with 512 byte blocks, while Figure 2(b) shows the reduced size in terms of projected volume's percentage. Figures 3(a) and 3(b) show the respective results for the *mozart* traces, again with 512 byte blocks. The *hplajw* trace showed results similar to these 512 byte block traces, with reductions falling between 91% and 97%. The interesting difference is that the *hplajw* trace does better early on, then quickly falls to 91% reduction before flattening out. The *iTunes* traces showed reductions similar to the *ranin* workloads, exceeding 98% reductions for small (512 byte) blocks.

As expected, larger traces show higher consistency in the necessary data required for storage. Smaller data sets would not adequately capture the larger picture, and would have new blocks introduced quite frequently, while larger sets would add only the occasional new block.

An interesting result to note is that total required storage space, after reductions, is reasonably consistent across block sizes, varying only by about 20%, while the total number of blocks that need tracked increase 14-fold. For instance, the full *ranin* trace, at roughly a month in length, requires about 150 to 189 MB, de-

(a) total space

(b) space reduction

Fig. 2. Comparison of total projected metadata storage versus reduced storage for all *ranin* traces with 512 byte blocks.

pending on block size, while the total number of blocks jumps from about 12 million (for 8 KB blocks) to 119 million (for 512 byte blocks). It is also interesting to note that, for *reduced* sizes, it is the middle block size of 4096 that requires the most space. As expected, the smallest block size has a much higher reduction rate, as it would exhibit a far greater amount of predictability, while the largest block size has far fewer blocks to track.

VI. Conclusions

In this paper, we have presented a simple yet novel strategy for tracking first-successor metadata information at the block level. We have provided an estimating function for showing the expected savings, based on

Fig. 3. Comparison of total projected metadata storage versus reduced storage for various *mozart* traces with 512 byte blocks.

the number of successors that are tracked and the percentage of blocks that have the next sequential block as their only successor, called heir apparents. Estimates show savings of around 90 to 99% over total space usage from prior strategies for heir apparent percentages exceeding 90%. This space usage, according to our formula, also scales reasonably well, growing linearly in the number of successors tracked. These estimates were then verified with simulations tracking this successor information and calculating how much space is used by our implemented structures, both before and after our reduction strategy. Multiple workloads with multiple block sizes were run, each showing large reductions, verifying that heir apparent percentages are quite commonly very high. We have shown that, with an overhead of only a few hash table lookups, we are able to reduce the required metadata

TABLE II. Comparison of total space of all *ranin* traces. Block size, projected size, and reduced size are given in number of bytes.

size up to 99%, and in all cases tested reducing required space to less than 200 megabytes, even for the largest workloads used. This first order successor information has been shown in previous work to be useful for prefetch prediction and caching as well as disk layout management.
